

The Price of Doing Business: Why Replaceable Foreign Firms Get Worse Government Treatment*

Leslie Johns[†]

Rachel L. Wellhausen[‡]

18 November 2019

Abstract

We argue that a host government treats foreign firms worse if those foreign firms have more replacements. We identify a key structural determinant of replaceability: the costs foreign firms must incur in order to begin production. Since the host government can only take from foreign firms that actually produce in its market, it must treat foreign firms better when their startup costs are high, lest the government drive all foreign firms out. Our innovative theoretical model adapts contemporary trade theory; applies it to the novel setting of foreign investment; and provides insights about the understudied relationship between foreign and domestic firms. Most importantly, it endogenizes market entry and exit, establishing the importance of entry despite scholars' long-time focus on exit. Our analysis uses cross-national firm-level data on taxes and production outcomes in up to 284 disaggregated industries, and we provide a new industry-level measure of government treatment of foreign firms.

1 Introduction

A canonical argument in political economy is that an individual who can more profitably exit from an institution has more power to secure her preferred outcome within that institution (Hirschman, 1970). This leverage is particularly important in international relations because the anarchic nature of the international system allows states to act independently and violate existing cooperative agreements (Johns, 2007; Voeten, 2001). Yet the role of exit may be overstated when considering the power of firms within the global economy. Unlike states, which cannot be easily replaced in the international system, the exit of one multinational corporation can often be offset by the entry of a new one.

Consider the Trump International golf course in Aberdeen, Scotland. After a large offshore windfarm within sight of the course was proposed in 2012, Donald Trump wrote to the Scottish Prime Minister that the “monstrous turbines” would turn the country into “a third world wasteland that global investors will avoid.”¹ Trump has tweeted about this at least sixty times, complained to the Scottish Parliament, taken a court case to the UK Supreme Court, and pressed onetime UKIP leader Nigel Farage to cancel the project.² Nonetheless, the Scottish government approved the plans, and the first of eleven planned turbines went up in April 2018. Why have Trump’s complaints gone unaddressed? Shouldn’t Scotland fear that Trump will pull his investment, leaving the Scottish economy in the lurch?

Conventional political economy accounts might emphasize that Trump cannot take his investment and leave: the golf course cannot be packed up and moved. Yet Trump spent relatively little money developing the golf course in the first place, and the equipment used to maintain the course can be easily moved to another location. We argue that the central feature of Trump’s dilemma is not that he has sunk a lot of money into assets that cannot be moved, but rather that he is easily replaceable (especially in the home of golf). The costs of building a golf course are relatively trivial; it would be relatively easy for a new investor to start her own golf course, even if she had to purchase new equipment and rebuild the golf course from scratch. We suggest that low startup costs—which lead to high replaceability—are a key explanation for Trump’s inability to get his way. There would be another firm waiting in the wings to replace the Trump Organization were it to exit—which it has not.

Our key contribution is to consider the political effects of *startup costs*: the one-time costs a

firm must pay to enter a market. Think of the minimum, break-even amount a firm needs to invest to begin production, such as building a factory, renting office space, acquiring basic machinery, or otherwise. While quantifying this concept requires considerable humility, we intend the reader to share our baseline intuition that such a concept exists: a firm clearly incurs costs in order to make its first dollar in a new market. We also intend the reader to share two key intuitions about how this concept varies. First, startup costs vary as a result of exogenous, structural aspects of the firm’s sector: the costs necessary to earn one dollar in revenue in a new market differ depending on whether that revenue comes from an oil refinery, a management consulting business, a retail store, or a lumber mill.³ Second, and crucially, aspects of the host state market that are exogenous to the firm also generate variation.⁴ The costs necessary to earn one dollar of revenue from operating a 5G network vary as a result of geography, population, GDP per capita, transportation, infrastructure, the depth of local financial markets, the availability of predecessor technologies, etc. Our aim here is to conceptualize these exogenous startup costs in a host state independent of costs at entry that are endogenous to politics. Thus, one contribution of our approach is to elucidate how firm decision-making is shaped by the exogenous, structural aspects of the host state market, upon which government actions at entry—from investment incentives to FDI restrictions—are layered.

Structurally-determined startup costs have crucial implications for how a host government treats foreign firms, a fundamental issue in the politics of foreign investment. In brief, low startup costs mean that new foreign firms can easily replace existing firms that choose to exit a market. The host government can therefore take more from foreign firms that face low startup costs, and be less concerned that such takings will deter future economic activity because replacement foreign firms can afford to enter the market. Conversely, when firms in a given industry must pay higher startup costs to begin producing goods and services in a given host state market, entry is more cost-prohibitive. Thus, foreign firms that exit the market are less likely to be replaced by new foreign firms, so high government takings are more likely to deter future economic activity. As a result, the host government does what it can to offset the burden of startup costs in these industries by offering favorable treatment to foreign firms that limits the costly burden of entry. This logic generates our main, novel hypothesis: for foreign firms, higher startup costs are associated with better government treatment. Moreover, our account establishes that the association between high startup costs and

³Our consideration of this variation expands on the well-known result that the costs of redeploying assets is a key, structural determinant of government treatment via “obsolescing bargains” (Vernon, 1971; Kobrin, 1987; Frieden, 1994).

⁴To be precise, there exist characteristics of the host state market that are plausibly exogenous to the firm in the short-run relevant to firm decision-making.

favorable treatment remains year-in and year-out, not simply at entry. One implication is that, in the context of high startup costs, government treatment aids “superstar” multinationals—with the particular ability to operate abroad—in further consolidating their dominant position.⁵ Yet at the same time, more concentration among “superstar” multinationals has the potential to open space for domestic competitors, given that consumers appreciate the variety of products that such smaller, less productive firms can supply.⁶

To establish the political importance of startup costs, we examine government treatment of foreign firms using a firm-level political economy model of foreign direct investment in a host state with multiple industries. Importantly, our model accounts for not just foreign but also for understudied domestic firms in a host state. We model a host government that regulates its own market, and can take rents from foreign firms using regulatory policies that discriminate between domestic and foreign firms. We allow both foreign and domestic firms to enter and exit the market over time in response to government policies and changing economic conditions. Our theory allows us to generate precise expectations about host government treatment of foreign firms, as well as attributes and economic outcomes of firms that choose to produce in a market.

We aim to creatively test observable implications of our theory, given empirical limitations in matching our theoretical concepts to data. First, we develop a novel measure of startup costs using firm-level data on listed firms in up to 284 disaggregated industries in up to 212 host states (2008–2016). We also introduce a novel measure of government treatment by averaging the tax burden faced by 20,786 listed foreign firms by industry-country-year. We show that higher industry-average startup costs for foreign firms in a given host state are associated with lower tax outlays.⁷ We also show that higher foreign tax burdens increase the divergence between observed foreign and domestic firm productivity, consistent with our expectation that small domestic firms can find more space to sell their product varieties in markets characterized by concentrated foreign investors. We further support our argument with empirical tests that leverage the selection effects in our model, namely, that foreign and domestic firms are selecting to both enter and exit the market over time.

This paper makes key theoretical and empirical contributions to political science. Our

⁵As such, our approach elucidates a key mechanism explaining the empirical finding that increased economic openness correlates with increased market concentration (Baccini, Pinto and Weymouth, 2017).

⁶This finding sets the stage for future research on otherwise unexpected cooperation between big multinationals and domestic firms (Weil, 2018; Hearson, 2018).

⁷Our article does not offer a theory of optimal taxation. Rather, we introduce firm-level tax data as a creative proxy for differential government treatment of FDI, a key research topic in international political economy. Nonetheless, we hope that by employing tax data, we might encourage further scholarship on the role of taxation in foreign investor-host state relation in the vein of Wallerstein and Przeworski (1995) and Hallerberg and Basinger (1998).

theoretical model adapts existing formal models of international trade with firm heterogeneity (Melitz, 2003; Melitz and Redding, 2014), which a spate of important political science scholarship has tied to the politics around trade policy (Gulotty, 2017; Baccini, Pinto and Weymouth, 2017; Kim, 2017; Osgood et al., 2017; Owen and Quinn, 2016; Queralt, 2017). Our model substantially expands on prior trade models by modeling government policies and market entry and exit as strategic decisions. We expect these modeling innovations to be applicable to a variety of work in political economy. Indeed, we apply our innovations on modern international trade theory in a novel substantive realm: the study of the political economy of foreign direct investment. Further, this paper makes an important empirical contribution by identifying, measuring, and disseminating a previously unexamined determinant of cross-industry and cross-country variation in government treatment: the (exogenous) startup costs paid by firms that enter a market. Together, our theoretical and empirical innovations allow us to establish how structural constraints on producing abroad shape the extent to which host governments can pursue their domestic agendas while still attracting foreign capital.

2 Determinants of Government Treatment of Foreign Firms

A rich literature in international political economy examines how a host states' political institutions and domestic politics shape government treatment of foreign firms. Scholars have demonstrated the influence of many such factors, including: regime type; federalism; government turnover (especially between capital- or labor-friendly parties); benefits for unskilled workers; and dependence on international institutions like the IMF or the World Bank (Jensen, 2006; Li, 2009; Pandya, 2010; Pinto, 2013; Biglaiser, Lee and Staats, 2016; Jensen et al., 2012).

At the same time, foreign firms' attributes influence their treatment by host governments. Scholars have been particularly interested in the implications of a firm's ability to exit for its leverage over a host government. The logic is that when firms invest abroad, they expose themselves to poor treatment by the government of the host (receiving) state. This problem is thought to be most acute for firms that make longer-term investments and acquire at least some managerial control over operations abroad through foreign direct investment (FDI). Host governments that are eager for the positive developmental effects of FDI have reason to lure investors in with the promise of favorable regulatory treatment (Pandya, 2014; Jensen and Malesky, 2018; Jensen, Malesky and Walsh, 2015). Yet even if a host government is genuine when making initial promises, sometimes it may later wish to retract incentives, increase environmental or labor standards, or increase cor-

porate taxes. The expectation born of the “obsolescing bargain” theory is that when firms cannot profitably exit their existing investments in response to such policy changes, the host government can continue to benefit from their FDI even as it changes the regulatory environment (Vernon, 1971). To explain variation in firms’ ability to exit, scholars have converged on industry-level asset mobility, or the extent to which a foreign firm can recoup and redeploy its initial capital outlay when it exits a market (Kobrin, 1987; Frieden, 1994; Jensen and Johnston, 2011; Hajzler, 2012). When a foreign firm in a low-mobility industry invests, it cannot easily recoup its initial investment in response to changes in the regulatory environment.

We argue that the scholarly literature focusing on exit comes with several limitations. First, arguments about the effects of exit on government treatment often hone in on extreme forms of treatment, particularly direct expropriation and government breach of contract (Li, 2009; Wellhausen, 2015*a*; Jensen et al., 2012; Graham, Johnston and Kingsley, 2016). We do not presume that adverse government treatment necessarily results in such severe property rights violations. Instead, we widen our focus to the relationship between attributes of firms and the array of government policies relevant to them, such as subsidies, environmental and labor policies, and taxation. In doing so, we highlight that government treatment of foreign firms can be marked not just by extreme, unlawful events, but also by relative stability.

Second, literature on the potential for exit by foreign firms has overlooked the role of domestic firms in the market, and specifically the host government’s priorities when it comes to domestic firms.⁸ As economic globalization has deepened, perceptions that foreign firms are privileged over domestic firms have contributed to frustration with FDI. For example, critics point to the fact that modern international investment law designed to protect property rights applies only to foreign, and not to domestic, firms (Waibel, 2010). Host governments are engaged in a delicate balance as they work to attract FDI while nonetheless promoting domestic entrepreneurship, especially in middle-income and developing countries. For example, Hungary has famously welcomed foreign ownership since it underwent economic transition in the 1990s, which has led to foreign dominance in high-profile industries. In the 2010s, a key part of the far-right Orban regime’s rhetoric has been to “politicize dependency” and prioritize domestic firms. Yet such rhetoric exists alongside the “quiet politics” of continued subsidies to FDI in manufacturing (Bohle and Greskovits, 2018). We take the host government’s interest in balancing between foreign and domestic firms seriously, particularly by examining how the host government’s treatment of foreign firms affects economic

⁸For notable exceptions, see Kosova (2010) and Betz and Pond (2019).

conditions for domestic firms.

Third, and most importantly, that the literature has taken exit as its starting point has led to neglect of the potential role of entry in shaping government regulation. Literature focused on exit typically rests on implications of exit for entry. For example, scholars who theorize around exit often invoke reputation-based arguments, such that mistreatment of one foreign firm impacts entry by other foreign firms (Tomz, 2007; Li, 2009; Allee and Peinhardt, 2011; Albertus and Menaldo, 2012). Yet even if reputation effects exist among current and potential foreign investors, prior adverse government treatment need not drive future FDI to zero (Johns and Wellhausen, 2016), nor does it appear to do so in practice (Wellhausen, 2019). By taking entry as our starting point, we engage with the reality that the deterrent effect of (the threat of) exit is probabilistic: when one firm exits a market, another sometimes enters the market and replaces it. This allows us to take seriously the proposition that a host government's ability to set its preferred regulatory policies is affected by explanations for entry beyond those derived from the implications of exit.

In theorizing around entry, we depart from the existing literature by examining the impact of a previously-ignored industry attribute: startup costs, or the one-time upfront costs of establishing new production. Think of startup costs as the minimum, break-even amount that a firm needs to invest in order to begin production in a given industry and country. Startup costs can include the costs of buying necessary machinery at the prevailing world price and shipping it to the new location. They can also include things like the construction costs of building new facilities or the rental costs of acquiring office space. If a firm finds the local infrastructure insufficient to facilitate transport of produced goods, startup costs can include the cost of activities like cutting and paving roads. We imagine that executives can and do know the costs of establishing facilities in a given industry and a given physical environment. We conceptualize startup costs as exogenous, although we consider at length below aspects of startup costs that are endogenous to government treatment at entry.

We argue that startup costs influence a host government's treatment of foreign firms. This treatment is achieved via regulatory policies that transfer utility from foreign firms to the host government. Such policies can include confiscatory takings, as well as perfectly legal and legitimate forms of regulation, such as environmental rules, labor protections, and taxation. Any regulatory policy that raises the cost of production for a foreign-owned firm and provides utility to the host state matches our conception of government treatment.

Like the obsolescing bargain literature, we allow firms to exit a market in response to

changes in government policy. However, unlike the obsolescing bargain literature, we allow such firms to be replaced by new foreign investors that choose whether to enter the market. Such entry and exit decisions are driven endogenously by government policies. We argue that higher startup costs reduce the likelihood the new foreign firms will enter a market, thereby inducing the host government to provide better treatment to existing firms. We additionally include asset mobility in our model to demonstrate that our argument is a complement, rather than a competitor, to existing research.

Exogenous startup costs are theoretically interesting, because they influence political decision-makers via their implications for the replaceability of firms: how easy is it to find an alternative investor to replace a firm that exits the market? Government behavior is influenced by startup costs, because a host government cares about its ability to seize rents in both the short- and long-term. Higher government takings increase the amount that the government receives from each unit of foreign production, but reduces the overall amount of foreign production, because higher takings drive existing firms from the market and make it less attractive for new firms to enter. As foreign startup costs increase, the entry problem becomes exacerbated: entry by new foreign firms becomes even less likely, meaning that a government must lower its takings rate in order to maximize its overall rents. Therefore, the selection processes that are driven by variation in startup costs result in variation in government takings. Market forces implicitly and endogenously affect the host government's treatment of foreign firms.

By modeling interactions at the firm-level, we can provide the theoretical microfoundations for why some firms select into participation in the global economy through FDI and others do not. This approach also comes with empirical benefits. As we describe below, we take a novel and, in our judgment, compelling approach to measuring government treatment via tax burdens. Yet we cannot be confident that tax burdens characterize the full spectrum of government treatment of foreign firms. However, our model allows us to derive indirect tests of our causal mechanism by examining the attributes of firms that select into FDI, including the productivity of foreign and domestic firms, and foreign firm revenues. Thus, we can use relationships between our variables of interest and standard measures of financial concepts to provide indirect evidence in support of our political economic theory.

3 Theory

Our model of FDI is based on the economic microfoundations of contemporary trade theory, as established in Melitz (2003) and subsequently extended to economies with multiple industries by Melitz and Redding (2014).⁹ In these trade models, firms decide whether to produce goods that can be sold in the firm’s domestic market and/or exported abroad for sale in foreign markets. Firms differ from one another based on both the unique goods that they produce,¹⁰ and their inherent productivity in producing their good. In every period, a small portion of firms experience an exogenous shock that causes them to “die”, or go out of business. Melitz (2003) and subsequent follow-on papers assume that the market has a stationary structure, as the firms that exogenously exit the market are replaced by new firms that endogenously decide to start new production.¹¹ The main result in Melitz (2003) is that exporting firms must be more productive than firms that just produce for the domestic market, because they must overcome the added exogenous transportation costs for exporting goods to foreign markets.

Rather than modeling trade across countries, we instead model decisions by both domestic and foreign-owned firms about whether to invest in the production of goods within a single market. Just as Melitz (2003) assumes that exporters face added transportation costs, we assume that foreign-owned firms face the potential for discriminatory treatment, in which government takings increase the marginal cost of production for foreign-owned firms.¹² Our theory includes two major innovations that accord with our substantive focus on FDI. First, we assume that government takings are endogenously chosen by a strategic host government (and hence are not exogenous, like Melitz’s transportation costs). Second, we assume that firms endogenously choose whether to exit the market (unlike Melitz, which assumes that a small portion of firms exogenously dies). Domestic and foreign-owned firms thus both enter and exit the market over time in response to changes in their firm-level productivity, which we allow to fluctuate over time. Other factors that affect entry and exit decisions are: the startup cost of beginning production, the mobility of capital that has previously been invested in production, and the treatment provided by the host government to foreign investors.

⁹These microfoundations are used in almost all contemporary trade theory models that introduce firm-level heterogeneity.

¹⁰That is, firms engage in monopolistic competition, per Dixit and Stiglitz (1977).

¹¹This concept of market stationarity with firm-level entry and exit was earlier developed in Hopenhayn (1992).

¹²Here we focus on the treatment of foreign firms for substantive reasons, in keeping with a substantial body of work that examines adverse government treatment of foreign firms relative to domestic firms (for an overview, see Graham, Johnston and Kingsley 2016). However, as discussed below, our framework can also be extended to examine the treatment of domestic firms as well.

3.1 Model Primitives and Structure

We focus on the unique stationary equilibrium of an economy of a single country that has $J + 1$ industries and a labor force of size L . We assume that industry $j = 0$ produces a homogenous good, which serves as our numeraire good. We assume that all other sectors ($j = 1, \dots, J$) produce differentiated goods. Firms can be either domestically- or foreign-owned, and each firm can produce a unique good from a set of industry-level varieties, $v \in V_j$. Whether a firm actually produces its good is an attribute of equilibrium behavior. At any given point in time, there are both domestic and foreign firms that are currently producing for the market; we describe these producing firms as being “in” the market. Similarly, there are also domestic and foreign firms that are not currently producing for the market; we describe these latent firms as being “out” of the market.

We assume that consumers have a preference for a variety of goods within an industry, and let $\sigma > 1$ denote the constant elasticity of substitution across goods within an industry. These consumers both buy goods and serve as the labor force that produces these goods. We let $q_j(v)$ denote the quantity of consumption of a specific variety v in industry j , and we let w_j denote the relative weight that consumers place on goods across industries, such that $\sum_j w_j = 1$. Consumer utility from aggregate consumption (across all industries) is:

$$U = \sum_{h=0}^J w_h \log Q_h \quad \text{where: } Q_j \equiv \left[\int_{v \in V_j} q_j(v)^{\frac{\sigma-1}{\sigma}} dv \right]^{\frac{\sigma}{\sigma-1}} \quad (1)$$

The index Q_j represents consumer utility from consuming the goods produced by industry j using the standard functional form in the monopolistic competition literature, as first introduced by Dixit and Stiglitz (1977). Consumers must optimize their utility subject to the budget constraint:

$$\sum_{j=0}^J \int_{v \in V_j} p_j(v) q_j(v) dv \leq R \quad (2)$$

where $p_j(v)$ is the price of good v in industry j , and R is aggregate revenue.

The game takes place over discrete time periods. At the start of every period, there are four different groups of firms in each industry. First, there are both foreign and domestic firms that are already “in” the market because they produced goods in the previous period. Second, there are both foreign and domestic firms that are “out” of the market because they did not produce goods in the previous period. In each period t , the game begins when each firm decides whether to pay a

small informational cost, $\beta > 0$, to learn its type for that period, φ . This type variable corresponds to the firm’s productivity in producing its unique good. Each firm’s type variable is independently and identically distributed across both players and times. We assume that Nature chooses a firm’s type (i.e. productivity) according to the Pareto distribution. A firm cannot produce without first learning its type.¹³

The government then announces a takings rate for each industry, τ_j , which corresponds to the amount per unit of production that the government takes from each foreign firm in industry j .¹⁴ After hearing the government’s announcement, each firm decides whether to produce its good in that period. Those firms that are currently “out” of the market (meaning that they did not produce in the previous period) can choose to either remain out—without incurring any additional costs or generating any revenue in the market—or enter the market and begin producing goods for sale. As shown in Figure 4, firms that are “out” of the market must pay a startup cost, κ_i , in order to enter the market and establish production facilities.¹⁵ We allow the startup costs faced by domestic firms, κ_d , to differ from the startup costs faced by foreign firms, κ_f .¹⁶ In contrast, firms that are “in” the market at the beginning of the time period (because they established production facilities in prior periods) can decide either to stay in the market and produce goods in period t , or to take their mobile capital and leave the market. We measure mobility as the share $\mu_i \in [0, 1]$ of startup costs that a firm can take when it leaves the market. We allow the mobility of domestic firms, μ_d to differ from the mobility of foreign firms μ_f .¹⁷ We assume that this decision about whether to stay or leave the market must be made prior to the actual production of goods in any given period.¹⁸ Over time, we allow firms to move both in and out of the market multiple times; that is, we do not assume that firms “die” based on exogenous and unexplained shocks, as in Melitz (2003). A firm’s decision to exit a market can always be reversed in a future period, albeit after paying the informational cost (to learn its productivity for that period) and the startup cost (to

¹³The cost of learning type can vary across foreign and domestic firms, across firms that were “in” or “out” of the market in the previous period, and across industries. If the information cost varies across firms that are “in” and “out”, the magnitude of this different must be limited, as detailed in the Appendix. This informational cost can be arbitrarily small, but is necessary in models of market competition to ensure that there is stability in a market’s size over time.

¹⁴To simply our presentation, we assume that this taking does not apply to domestic firms. Empirically, we measure the takings rate as the amount taken in tax per production as accounted for by pretax income.

¹⁵Throughout this discussion we suppress the notation for different industries for the sake of clarity.

¹⁶For the results we present here, we do not need to make any assumptions about which type of investor has higher startup costs.

¹⁷For the results we present here, we do not need to make any assumptions about which type of investor has higher mobility.

¹⁸So if a firm produces goods in a given period, it must wait until the next period before it can again decide whether to exit. This accords with the definition of startup costs as the fixed assets necessary to produce goods.

re-enter the market).

[Figure 4 goes here.]

We assume that production uses only one input, domestic labor, and there is a fixed production cost in each period, $c > 0$, which is measured in terms of a unit of labor. For a firm with a productivity φ , we let $p(\varphi)$ denote the price and $q(\varphi)$ denote the quantity of the differentiated good produced by the firm. The profit function for a domestic firm is accordingly:

$$\pi_d(\varphi) = p_d(\varphi)q_d(\varphi) - \left[\frac{q_d(\varphi)}{\varphi} + c \right]$$

Higher levels of productivity therefore correspond to lower unit production costs. Since a foreign firm must pay an additional per unit taking to the government, its profit function is:

$$\pi_f(\varphi) = p_f(\varphi)q_f(\varphi) - \left[\frac{q_d(\varphi)(1 + \tau)}{\varphi} + c \right]$$

Note that this profit function assumes that more productive firms can both produce goods and pay the government takings rate at a lower cost in units of labor.

3.2 Equilibrium Behavior

The full derivation of equilibrium behavior is included in the Appendix. We begin by examining market behavior after the government has announced its takings rate for each industry:

Proposition 1. *For any given takings rate, $\tau \geq 0$, there exist types x_i and y_i , for $i = d, f$, such that $0 < x_i < y_i$. Firms that are in the market decide to exit if $\varphi < x_i$, and stay and produce if $x_i \leq \varphi$. Firms that are out of the market decide to stay out if $\varphi < y_i$, and enter and produce if $y_i \leq \varphi$.*

As shown in Figure 5, those firms that are already “in” the market will find it profitable to stay and produce as long as they have moderate or high levels of productivity ($x_i < \varphi$). If a firm that is already in the market has low productivity for the period, it cannot compete profitably against the other firms in the market; accordingly, it will exit, taking its mobile capital with it. However, those firms that are “out” of the market will only enter and pay the accompanying startup cost if they have high levels of productivity ($y_i < \varphi$). If their productivity is either low or moderate,

they cannot profitably pay the entry cost and compete against other firms in the market.¹⁹

[Figure 5 goes here.]

To understand strategic behavior by the government, we must first understand how changing the takings rate for an industry affects economic outcomes. When the government increases the takings rate, it increases the unit cost of production for foreign firms. This increase in production cost means that each foreign firm produces less and earns lower revenue. Since production is less lucrative, existing foreign firms are more likely to leave the market, and potential foreign firms are less likely to enter. The aggregate effect of these changes is that there is less aggregate production by foreign firms, but those foreign firms that do survive in the market are more productive. Simply put, higher government takings drives less productive foreign firms out of the market by raising cutpoints x_f and y_f . This selection effect raises the average productivity of those foreign firms that choose to produce.

While the (foreign) takings rate does not directly affect domestic firms, the changing behavior of foreign firms alters overall market conditions and thereby affects domestic firms. Since higher takings reduces the number of foreign firms in the market (by increasing x_f and y_f), it also reduces the variety of goods that are produced by foreign-owned firms. Because consumers prefer to consume a variety of goods, they will value the diverse goods produced by domestic firms. Accordingly, higher government (foreign) takings reduces market competition from foreign firms, allowing less productive domestic firms to enter and making them more likely to survive in the market. This corresponds to a decrease in cutpoints x_d and y_d . This selection effect lowers the average productivity of domestic firms that produce in the market. Both of these implications—about average foreign productivity and average domestic productivity—explicitly take into account what is observable by researchers, given the strategic behavior of firms in the market.²⁰

Proposition 2. *A higher government takings rate from foreign firms is associated with higher average foreign productivity and lower average domestic productivity.*

Given these market effects, we can now consider the host government’s decision about how much to take from foreign firms. Since the takings rate applies to each unit of foreign production,

¹⁹Low- or moderate-productivity firms cannot increase their productivity to profitable levels within a given period; for example, catching up to more productive firms via learning-by-doing within a given period is not possible.

²⁰It is possible that these selection effects change the dynamics of collective action among and between foreign and domestic firms that produce in the market, which is an important topic for future research.

the utility to the host government of the takings rate for an industry is simply:

$$W(\tau) = \tau Q_f$$

When choosing the optimal rate, the government must balance the benefit of increasing the takings rate against the cost of decreasing the number of units produced by foreign firms. This balancing process takes into account the impact of the takings rate on firm-level decisions about whether to enter the market, how much to produce, and whether to exit the market, which in turn affect the productivity of firms in the market.²¹ The host government can find a unique takings rate that balances these two competing factors in order to maximize its own utility.

Proposition 3. *There exists an equilibrium in which the host government chooses an optimal takings rate from foreign firms, and foreign and domestic firms operate in the resulting market equilibrium.*

3.3 Comparative Statics

Our model yields a wealth of possible comparative statics. Our main interest lies in the political effect of startup costs on government takings:

Proposition 4. *For foreign firms, higher startup costs are associated with a lower average government takings rate.*

The magnitude of foreign startup costs affects both entry and exit decisions by foreign firms. Holding asset mobility constant, when startup costs are low, it is relatively easy for new foreign firms to enter, and existing foreign firms have relatively little incentive to leave. Accordingly, cutpoints x_f and y_f are relatively low, and the government has a broad base of foreign firms from which it can take. As foreign startup costs increase, entry becomes less desirable for foreign firms that are out of the market: new foreign firms must be more productive to pay the higher startup costs, meaning that cutpoint y_f increases. At the same time, exit becomes more desirable for foreign firms that are already in the market. These firms must be more productive to be willing to stay, meaning the cutpoint x_f increases. This leads to an overall reduction in the base of foreign firms from which the government can take. To offset this decrease, the rent-seeking government

²¹As discussed below, in model extensions we adjust the government's objective function to take into account other additional factors, like domestic production, domestic productivity, and consumer welfare.

is best off if it lowers its takings rate in order to keep more foreign firms in the market.²² These dynamics ensure that high startup costs indirectly protect foreign firms: since it is more difficult to replace foreign firms when startup costs are higher, the government will treat them more favorably by taking less.

Unfortunately, it is difficult to accurately observe and measure the full spectrum of government treatment of foreign firms, which means we cannot avoid tradeoffs in empirical testing. It is therefore of paramount importance that our theoretical model allows us to state the implications of our theory for other standard, measurable economic outcomes. We next consider the average productivity of foreign firms that have selected into producing in the host country and, hence, are observable to researchers:

Proposition 5. *For foreign firms, higher startup costs are associated with higher average productivity when foreign asset mobility is high.*

Startup costs have both a direct economic effect and an indirect political effect on which foreign firms decide to produce. The direct economic effect of high startup costs is to deter low productivity foreign firms from entering the market. Simply put, a firm must be more productive in order to recoup the initial cost of entering the market. However, since governments can only take from those foreign firms that actually produce, high startup costs also cause the government to take less, per Proposition 4. So high startup costs have an indirect political effect by lowering government takings, which in turn allows less productive firms to produce, per Proposition 2. Which effect is stronger—the direct economic effect or the competing indirect political effect—depends on assumptions about the basic characteristics of the market. However, when a foreign firm’s mobility is relatively high, the level of government takings has a relatively small effect on firm decision-making. This means that the direct economic effect outweighs the indirect political effect of high startup costs. In industries with high foreign mobility, higher startup costs will be associated with higher levels of productivity for those foreign firms that choose to produce in the host economy.

We can additionally indirectly assess our theory using firm revenues, which are observable in our data. The overall impact of startup costs on firm-level revenues is positive for those foreign firms that are willing to produce:

Proposition 6. *For foreign firms, higher startup costs are associated with higher revenues.*

²²As discussed below, if the government also cares about consumer welfare, its choice of a taking rate will also take into consideration the impact on domestic production.

Since high startup costs deter new foreign firms from entering a market, they reduce competition and increase prices for consumers. However, startup costs are only paid when a firm enters a market, meaning that they are sunk costs by the time that a foreign firm begins actual production: they do not affect production costs after a foreign firm has entered the market. By increasing prices without increasing the production costs for those firms that have already entered the market, higher startup costs directly lead to higher revenues for foreign firms. Additionally, foreign startup costs indirectly increase firm revenues even further by pressuring the government to provide more favorable treatment. Both the direct and indirect effects of startup costs therefore lead to higher revenue for foreign firms.

3.4 Robustness

How robust are our results? We should begin by noting that the model above explicitly includes asset mobility and allows foreign firms to exit the market in response to alleged mistreatment by the host government. As such, our theoretical account is a complement to the standard obsolescing bargain logic, not a substitute for it. Our model highlights that while the previous literature’s focus on asset mobility and exit has yielded important insights, it has also caused us to overlook the equally important impact of startup costs and market entry. Readers who are substantively interested in asset mobility can use our modeling framework to derive implications that are consistent with prior research. Here we have chosen to emphasize our new findings, rather than simply restating logic that has been well-explored previously.

Readers might note that when we endogenized government behavior, we adopted a relatively simplistic objective function for the host government: we assumed that the host government seeks to simply maximize takings from foreign firms. These higher takings benefit domestic firms, but indirectly harm consumers within the country by reducing market competition. In a model extension (that is available upon request), we allow the host government to trade-off the direct benefits it receives from its takings against the indirect impact of these takings on consumer welfare. Not surprisingly, when the host government places more weight on consumer welfare, it extracts less from foreign firms. However, all of the basic results in our model continue to hold. We are careful in our empirical analysis below to account for possible variation across countries in their responsiveness to consumer welfare. As detailed below, host country and year fixed effects account for host country- and time-specific characteristics. Other state-level controls, particularly regime type and commitments to international investment law speak to within-country over-time variation

in the host government’s weighting of consumer welfare.

We also simplified our main analysis by assuming that the government only takes from foreign firms. However, the model can be expanded to allow for takings from either domestic or foreign firms (or both).²³ That is, we need not assume that the government is perfectly constrained in its treatment of domestic firms—just as the model above allows the government to choose takings from foreign firms, we can also allow the government to take from domestic firms. In the model extension with domestic takings, Propositions 1-3 always hold. Additionally, Proposition 4-6 hold whenever foreign mobility is relatively high or domestic takings are relatively low. These conditions have the effect of biasing of empirical tests away from the effects that we are trying to identify, making the task of identifying empirical effects even harder.

Our main substantive interest is in Proposition 4, which states that for foreign firms, higher startup costs should be associated with lower government takings. The argument that supports this logic is contingent on both (1) changes in startup costs in the country being observed, and (2) existing investors being able to recover a portion of their capital and redeploy it elsewhere. That is, when we consider the impact of increasing startup costs in a given country, we assume that investors have a credible exit option: they can recover a portion of their initial capital and engage in other profitable activities. These dynamics should be different if we consider the impact of startup costs in alternative markets or economic activities. Imagine an investor who has deployed her capital in a given country *A*. If startup costs increase in a different country *B*, then the real value of her mobile capital should decrease: the foreign investor will have a less credible exit option, which means that her firm will be a more attractive target for mistreatment. While high startup costs at home can discipline a host government, high startup costs in other markets may allow a host government to increase takings at home (since exit is a less desirable option). This suggests that there may be important competitive dynamics across countries that are currently missing in our model.²⁴ These kinds of competitive dynamics lie outside the framework of our current work, but pose an interesting possibility for future research.

Another limitation of our modeling framework is that we focus on government takings at the industry-level. We do not, for example, allow the host government to microtarget its treatment at the firm-level. It is unclear how relaxing this assumption would affect our results. A sophisticated government could ameliorate some of the entry and exit dynamics that drive our results by targeting firms for mistreatment based on their productivity. From a substantive perspective, it is unclear to

²³This model extension is also available upon request.

²⁴We thank Iain Osgood for highlighting this point.

us whether such behavior would be feasible, as a host government is unlikely to know the precise productivity of individual firms, which can change over time. But a host government could target firms based on production levels, revenues, or other observable attributes. We have chosen not to pursue the line of inquiry because our intuition is that forward-looking firms could anticipate possible microtargeting and adjust their production accordingly. While the distortions that would be created by such a scenario would be important for understanding consumer welfare and economic outcomes, we do not have any reason to believe that they would invalidate our substantive interest in political outcomes; namely, the impact of startup costs on government treatment of foreign firms.

4 Empirics

Our formal results allow us to construct a set of hypotheses. The first two hypotheses are direct claims about government behavior.

Hypothesis 1. *A higher government takings rate from foreign firms will increase average foreign productivity and decrease average domestic productivity within each industry. (Proposition 2)*

Hypothesis 2. *For foreign firms, higher startup costs will be associated with a lower government takings rate within each industry. (Proposition 4)*

We do our best to measure government takings so as to provide evidence consistent with Hypotheses 1 and 2; yet proxy measures of government treatment can only go so far. Therefore, our next two hypotheses involve standard, observable attributes of firms that select into FDI, which we can use to indirectly test our political-economic theory.

Hypothesis 3. *For foreign firms that are mobile, higher startup costs will be associated with higher average firm productivity within each industry. (Proposition 5)*

Hypothesis 4. *For foreign firms, higher startup costs will be associated with higher revenues at the firm-level. (Proposition 6)*

These hypotheses and their empirical tests are summarized in Table 1.

[Table 1 goes here.]

To empirically assess our theoretical argument, we must measure multiple outcomes of interest, including startup costs, government takings, and firm- and industry-level financials. To

do so, we use financial data collected in the Bureau van Dijk Osiris databases on industrial firms and their subsidiaries (2008-2016).²⁵ Our data include 86,906 publicly listed parent companies worldwide (on 200 stock exchanges) that report financials for at least one subsidiary in addition to the parent firm.²⁶ Firms originate in 149 home states and invest in 212 host states. We use data on firms in up to 232 disaggregated industries, measured at the 4-digit NAICS industry code level. For example, we analyze cement/concrete manufacturing (4-digit), rather than nonmetallic product manufacturing (3-digit) or manufacturing (2-digit).

We must measure several concepts separately based on whether ownership is foreign or domestic. The same parent company can be both domestic (in one country) and foreign (in one or multiple countries). A foreign firm reports financials for a subsidiary in a given host country, but its parent company's recorded home address is in a different country; there are 20,786 foreign firms in the data. A domestic firm must also own a subsidiary, but both the parent address and the subsidiary address are located in the same country. There are 86,859 domestic firms in the data.²⁷ Given that both being listed and operating a subsidiary are indicators of success, our sample of domestic firms is biased toward more competitive firms. This bias makes it more difficult for us to identify expected differences in productivity between foreign and domestic firms (Hypothesis 1).

4.1 Measuring Startup Costs

Our main variable of interest is `STARTUP COSTS (FOREIGN)`. The underlying concept we aim to measure is the minimum, break-even amount that a foreign firm needs to invest in order to begin production at a subsidiary in a given foreign setting. We proxy for this using the dollar value of fixed assets in the first year a firm operates in a given industry-country, recorded in firm income (P/L) statements. Now, accountants do not fill out income statements with our concept of startup costs in mind. Formal rules and informal norms in accounting vary by industry, given market-driven expectations, and by host state, given domestic accounting regulations and oversight institutions (Hopwood and Miller, 1994).²⁸ Usefully, industry and host state variation are import components of our theory as well. It is thus theoretically and empirically consistent to operationalize `STARTUP`

²⁵Bureau van Dijk Osiris Industrial and Osiris Subsidiary. `bvdinfo.com`. Accessed July 2017.

²⁶In the parlance often used for firm-level data, we mean that a firm that operates a subsidiary has at least one establishment in a given country. The Osiris databases also include some "important" domestic, unlisted firms in their databases. However, "important" is not well-defined, so we drop these firms.

²⁷Forty-seven of the total 86,906 listed parent companies in the data are foreign but are never domestic.

²⁸For example, capital expenses that we would conceptualize as startup costs can often be amortized over the useful life of the asset. Other startup costs for assets that do not need to be replenished would not typically be amortized. We assume that variation in accounting practices are plausibly exogenous to the firm in at least the short-run.

COSTS (FOREIGN) as the average across the value of fixed assets (USD millions, ln) recorded for the first year of operation of all foreign firm subsidiaries in a given industry-country—generating the average startup costs for, say, a foreign firm operating in the South African non-metallic mining sector (NAICS 2123). Averaging across firms in the relevant industry-country allow us to mitigate the effects of outliers while still generating a measure appropriate for testing our theory’s firm-level implications. Note that we conceptualize startup costs as time-invariant, which we see as appropriate given our short time window (2008-2016).²⁹ We follow the same process in calculating a second variable of interest, STARTUP COSTS (DOMESTIC).

Before moving on, we probe the validity of our startup costs measure and address endogeneity concerns. First, recall that our theoretical model is consistent with the literature in expecting asset mobility to affect government treatment via its implications for the credibility of firms’ exit threats (Frieden, 1994). The concept of startup costs is distinct from but related to asset mobility: if a firm that produces in the market subsequently exits, it can take mobile assets that can be redeployed in other activities or markets. Some of its mobile assets may have been a component of startup costs. However, we have no expectation that the relationship between mobile assets and startup costs is consistent across industries. Importantly, the data provide empirical support for our theoretical distinction between startup costs and asset mobility. Figure 1 categorizes industries by the standard, dichotomous measure of asset mobility used in the literature, although note that in our theoretical model we conceptualize mobility as a continuous variable.³⁰ Figure 1 also reports the average STARTUP COSTS (FOREIGN) across all host states at the 2-digit NAICS industry code level.³¹ Substantial variation both across and within categories suggests that startup costs are not another measure of asset mobility, and that they have the potential to add additional explanatory power.³²

[Figure 1 goes here.]

Second, a substantial literature in international business establishes that firms face a “liabil-

²⁹In the long run, changes in the technology employed in a given industry or endowments in host states could change startup costs.

³⁰Because our theory largely confirms established findings regarding asset mobility, we focus on other empirical innovations instead of refining the measure of asset mobility. Some have proposed that fixed assets classified as property, plant, and equipment (PPE) hold promise as a proxy for immobile assets (Kerner and Lawrence, 2014). However, some components of PPE can be redeployed across borders, and non-PPE assets can be immobile across borders (such as a license to operate), creating unpredictable measurement biases.

³¹We combine industries for which there are multiple 2-digit codes, such as manufacturing. Variation is even more prominent at disaggregated 3- and 4-digit levels.

³²In our data, mobile firms are significantly larger (measured by annual income; $p < 0.001$), which is one reason we account for this possible confounder in empirical analyses below.

ity of foreignness” when investing abroad, such that foreign firms incur higher operating costs than domestic firms in the host state (Zaheer, 1995). For example, foreign firms must coordinate across geographic distance; incur search costs in acquiring relevant local cultural and political knowledge; and adapt their standard operating procedures to local institutions (e.g. Beazer and Blake 2018; Jia and Mayer 2017; Zhu and Shi 2019; Eden and Miller 2004). Put in our terms, the “liability of foreignness” implies that we should record higher startup costs for foreign firms than for domestic firms. Figure 2 provides support that this is the case: startup costs are consistently higher for the average foreign firm than for the average domestic firm operating in the same industry.

[Figure 2 goes here.]

Third, we expect that structural characteristics of the host state market are a key, exogenous source of variation in startup costs. For example, while some host states have an abundance of natural resources, well-developed transportation networks, deep financial markets, and high GDP per capita, others do not. We conceptualize these kinds of host market characteristics as endowments that are plausibly exogenous to a given firm, at least in the short-run. Which specific host market endowments impact startup costs will depend on the needs of a specific industry. As a validity check, our startup costs measure should correlate with our intuitions about the rank ordering of startup costs across host states for a given industry. Figure 3 provides one such validity check using cross-national values of the average startup costs faced by a foreign firm in pharmaceutical/medicine manufacturing (4-digit NAICS). Ghana, Myanmar, and other poor countries have some of the highest startup costs in this industry. These countries have little preexisting infrastructure on which new firms can draw, so startup costs likely include large construction projects to build factories, acquisition of basic equipment from outside the country, and so on. In contrast, the wealthy country of Finland, with considerable preexisting infrastructure, has among the lowest startup costs. Some perhaps surprising countries like Barbados have quite low startup costs in this industry. Such small countries often play host to the financial arms of multinational corporations (in whatever industry), meaning that startup costs are more about renting office space. Variation in the kinds of production foreign firms tend to locate in different host state markets reinforces our careful attention to identifying empirical analyses off of cross-industry variation within a given host state. Again, in the long-run, host countries that invest in infrastructure, develop natural resources, or otherwise improve their endowments may be better able to lure in FDI.³³ However, in the short-run, such attributes are fixed and exogenous to a firm’s

³³Long-run technological improvements can also change relative startup costs across industries and host states that

entry decision.

[Figure 3 goes here.]

Consistent with the conceptualization in our theoretical model, we aim to measure startup costs that are exogenous to host government behavior. For example, our measure of startup costs should include the price a milling machine has on world markets, exogenous to the government in a particular host state. That said, we recognize that a host government can influence startup costs at the margin, complicating our presumption of exogeneity. For example, a host government might charge a tariff on the import of said milling machine.³⁴ Here, we discuss our approach to the difficult empirical task of separating exogenous startup costs from simultaneously-observed government treatment.

Specifically, we must address the empirical possibility that government treatment affects the value of fixed assets upon entry, our means of measuring startup costs. We know that host governments sometimes set regulations that constrain firms' investment decisions, such as local content requirements or required domestic equity in foreign-owned firms. Of particular concern is the contention that firms that expect better government treatment could choose to invest more upon entry—for example, by building a bigger factory.³⁵ If that were the case, then fixed assets upon entry would be not an exogenous measure but would be exactly determined by expected government treatment. We have several defenses of our measurement approach in response to endogeneity concerns. One reason we choose to use fixed assets as our measure of startup costs is that we see it as the measure of a firm's initial investment that is least vulnerable to endogeneity. Contrast choices over fixed assets with choices firms make over incurring variable costs at entry. Firms have an interest in responding flexibly to expected government treatment, because government treatment can vary over time. Firms can more flexibly respond to variation in government treatment through changes in variable costs, for example by hiring or firing workers. In contrast, shedding or constructing new facilities in response to changing expectations about government treatment is costly. In our data, the low correlation between employees and fixed assets in the first year of operation (0.24 for foreign firms, 0.15 for domestic) suggests that firm decisions on incurring initial variable and fixed costs are not interchangeable.

vary in access to technology.

³⁴While we focus on host states' potential to (on net) treat foreign firms adversely, states can and do endogenously affect costs at entry through positive incentives. We encourage future research that brings together findings about adverse and preferential treatment of foreign firms.

³⁵We thank Mike Tomz for highlighting this point.

Moreover, probing the data gives us confidence that the ordering of our startup cost measures is intuitive. For example, comparing across industries, startup costs are particularly high in utilities and particularly low in services (Figure 1). The foreign startup cost for information stands out as particularly high; this includes telecommunications (NAICS 517), which can involve massive investments in infrastructure to facilitate cell phone networks.³⁶ One source of endogenously lowered startup costs could be government-provided investment incentives for foreign firms at entry.³⁷ However, in the data any such dynamic is not lowering fixed assets to the point that they disrupt the empirical foreign-to-domestic relationship predicted by the literature, which is that engaging in FDI is more expensive than investing at home (Dunning, 1993; Zaheer, 1995). Recall that startup costs in the data are consistently higher for foreign firms than for domestic (Figure 2).

In short, we see empirical corroboration that fixed assets upon entry can speak to our concept of startup costs. Finally, as described below, our modeling strategy uses extensive fixed effects to further mitigate endogeneity concerns.

4.2 Measuring Government Treatment: Taxes

Our main political variable of interest is the government takings rate, which in our formal model is based on a straightforward transfer from the firm to the government. Our best approximation is to focus on taxes reported in firm income (P/L) statements. We note that by choosing to measure taxes, we are measuring indirect takings but not takings in which the government gains benefits from the firm directly. For example, instead of collecting taxes, the government could expropriate foreign property and, as owner, earn direct returns on production.³⁸ As we fully acknowledge, our theory is best tested with a measure of the full set of transfers—indirect and direct, monetary and otherwise—from foreign firms to a host government. Nonetheless, in the absence of such a measure, we see taxes as a particularly useful second-best for both empirical and theoretical reasons. Empirically, if tax rates are indeed relatively unimportant in explaining aggregate FDI flows (Jensen, 2012), this operationalization will make it more difficult to link government treatment to firm production decisions as predicted. Theoretically, tax burdens are a key component of differential government treatment, in that political decisions over taxes clearly

³⁶Given that such investments are site-specific, we further criticize standard binary breakdowns of mobility that assume away heterogeneity in mobility within aggregated industries (see again Figure 1).

³⁷It is again crucial that our analyses rely on highly disaggregated industries, as investment incentives are usually industry-specific (Jensen and Malesky, 2018).

³⁸One driver of the government’s decision to take via taxes or take via ownership is its expectation that it has the technology and intangible assets necessary to produce efficiently and profitably absent foreign ownership.

shape expected returns, yet their examination has been largely excluded from the literature on FDI in international political economy. To be clear, our use of tax data does not mean that this article is about optimal taxation.³⁹ Nonetheless, we hope our use of firm-level tax data might reinvigorate scholarship in the vein of important, early work on the role of taxation in foreign investor-host state relations (e.g. Wallerstein and Przeworski 1995; Hallerberg and Basinger 1998).

While firms report taxes in a variety of ways, our theory is based on actual takings by the government, or the cash tax expense. `CASH TAX EXPENSE` is effectively the amount paid out of the firm’s “checking account” and into the government’s coffers in a given year. It consists of the firm’s income tax expense, plus tax payable and deferred taxes at the beginning of the year, less tax payable and deferred taxes remaining at the end of the year. Unfortunately, cash tax expense is not recorded in standard income statements. We are able to back it out for 52.7 percent of foreign firms in the data, due to missingness on tax payable and deferred taxes. Analogous to their role in shaping `STARTUP COSTS`, industry and host state characteristics shape firms’ abilities to manipulate their tax bills through amortization, transfer pricing, and the like (Rixen, 2011). It is therefore important to average by industry-country in calculating a foreign firm’s (average) annual cash tax expense (USD millions, ln).⁴⁰ As explained below, we use weighted least squares to account for variation in the underlying number of observations built into our averaged measures. We emphasize to the reader that these data constraints further underscore the importance of the indirect tests of our theoretical model that rely on standard measures in income statements, for which we have effectively full coverage.

Our ultimate measure of interest is the `EFFECTIVE CASH TAX RATE`, which is `CASH TAX EXPENSE` divided by the firm’s taxable income. `PRETAX INCOME` is a firm’s revenue minus the costs of goods sold. Scaling government takings is particularly important, because heterogeneous trade theory establishes that larger firms are more likely to produce abroad. Thus, to test our novel predictions about the relationship between government takings and production decisions, we must account for size. Consistent with best practices in accounting, pretax income is the appropriate measure for size in our context.⁴¹ To test our model’s predictions, we again calculate the annual

³⁹Recall that in endogenizing government behavior, we assume the host government seeks only to maximize takings from foreign firms. See again Section 3.4 Robustness for discussion of this assumption as well as model extensions that incorporate distributional effects on consumer welfare (available upon request).

⁴⁰We shift the data to avoid logging negative values; we suggest that scholars interested in investment incentives consider firm-level data on negative tax expenses.

⁴¹Results are robust to scaling by `EARNINGS BEFORE TAX`, which is income before corporate tax and unusual/exceptional after-tax items, but after depreciation, amortization, and deducting interest expenses. See replication files.

average for a foreign firm by industry-country, and again shift the data and take the natural log.

4.3 Additional Measurement and Design Choices

We further rely on best practices in accounting in measuring productivity as the RETURN ON ASSETS, which is a firm’s net income divided by its total assets.⁴² To generate our productivity measures of interest, we generate average firm-level ROA by industry-country-year and again shift the data and take the natural log. We do this separately for foreign firms and domestic firms. Our final dependent variable, foreign firm REVENUE, is equivalent to sales, or the amount earned from a firm’s main activities. Our theory generates implications for revenue at the firm-level, which is the total revenue reported by the listed parent company in a given host country (meaning that we do not need to average firm-level data across the industry-country). At least part of a parent company’s total revenue in a host country can be traced to the subsidiaries the parent company operates in the host country.⁴³ Helpfully, our data are granular enough that we can also assess our theory with subsidiary-level revenue.

A key control variable is MOBILE, which is the standard dichotomous measure of mobility versus immobility based on intuitions about industry, per the literature (see again Figure 1). Unfortunately, this dichotomous measure leaves heterogeneity within broad industry categories unmeasured. For example, mobility certainly varies between a steel mill and a textile mill, but both are categorized under (mobile) manufacturing. As discussed above, the absence of a continuous measure of mobility constrains scholars’ (including our) ability to fully test theoretical implications. Nonetheless, we expect coefficients on even the imprecise MOBILE to track the logic of the obsolescing bargain. Most importantly, we expect that STARTUP COSTS are a key explanatory variable even when controlling for mobility.

Unmeasured heterogeneity across industries, with regard to mobility or many other characteristics, could bias our estimations. For example, a firm’s potential to have a high RETURN ON ASSETS is determined in part by its capitalization. The more capital-intensive a firm, the more difficult it is to achieve a high ROA. To address cross-industry heterogeneity, we first measure industry at a very disaggregated level (4-digit NAICS). Next, in every specification we include fixed effects for INDUSTRY (3-DIGIT). Thus, our cross-industry comparisons are nested within an

⁴²We see it as a benefit that our income-statement data allow us to capture a common productivity measure that accountants calculated—and executives (and tax collectors) have seen—rather than manipulate input/output data to generate other productivity measures.

⁴³A parent company could also earn revenues through royalties or other activities that may not be reported on the income statement of a particular subsidiary.

already disaggregated industry that allows us to compare across groups of firms that are likely to have similar mobility, capital-intensity, and other characteristics. For example, our identification process leverages variation across the average firm in pharmaceutical/medicine manufacturing (NAICS 3254) and the average firm in an industry like pesticide, fertilizer, and other agricultural chemical manufacturing (NAICS 3253), while controlling for the higher-order category of chemical manufacturing (NAICS 325).

There are a number of other potential sources of unmeasured heterogeneity that we address with further fixed effects. `HOST STATE` accounts for country-specific characteristics that could bias our estimates; for example, countries differ in domestic institutions that could influence our outcomes of interest (Dorsch, Mccann and Mcguirk, 2014). This heterogeneity is also an important reason we measure startup costs by industry-country. We control for the `HOME STATE` of each firm, which speaks to possible variation in treatment resulting from bilateral dynamics (Wellhausen, 2015*b*). `YEAR` fixed effects account for annual shocks that could interfere with our estimations, such as effects of the Great Recession. These extensive fixed effects also relate to endogeneity concerns. Accounting for host state, home state, year, and the overarching 3-digit industry, we expect any endogenous component of `STARTUP COSTS` to be randomly distributed across 4-digit industries. We see it as reasonable to expect that, within the agricultural industry of crop production (111), a given host state’s influence on fixed assets upon entry (among firms from the same home state, in a given year) would not be systematically related to the choice of farming vegetables and melons (1112) or fruit and tree nuts (1113). Additionally, we include time-varying country-level covariates. `BITs` (Bilateral Investment Treaties) counts the cumulative number of international investment agreements ratified by the host state, expected to correlate with the government’s overall attitude toward and treatment of FDI. We also include `FDI NET INFLOW PER GDP`, `DEMOCRACY` (-10 to 10 Polity IV scale), `TRADE PER GDP`, and `GDP PER CAPITA (ln)`.⁴⁴

Recall that many of our variables of interest are averages. Our theory is built on expectations about firms entering and exiting the market, which means that industry-country-year observations are based on different sets of firms at different times.⁴⁵ Thus, it is appropriate to account for heterogeneity in the set of firms that feed into observations per our unit of analysis. In so doing, we also address missing data that can cause variation in the precision of our averaged

⁴⁴Sources: UNCTAD, the World Bank World Development Indicators, and the Polity project.

⁴⁵One could interpret our theoretical model as having implications for the number of firms underlying each observation, which would make the precision of our averaged measures endogenous to the theory. However, note that the same ownership structure can extend over different actors’ decisions to select in or out of production, so we avoid inferences based on counts of the number of different named parent companies. We thank Timm Betz for discussion.

measures. The best approach is to rely on the long-standing strategy of weighted least squares. Our empirical target is a population, and weighting moves our data sample closer to measures of that population. Employing weighted least squares allows us to more accurately account for non-random variation in the precision of our underlying data (Angrist and Pischke 2009: 92).⁴⁶ Finally, we are able to indirectly test our political expectations with individual firm-level data (Hypothesis 4) rather than averaging across firms within industry-country categories. This allows us a further opportunity to find support for our model while mitigating aggregation problems.

4.4 Regression Results

In testing Hypothesis 1, we expect the coefficient for EFFECTIVE CASH TAX RATE (FOREIGN) to be positive for foreign firms and negative for domestic firms, as the government takings rate from foreign firms has opposing effects on observed productivity (RETURN ON ASSETS) by ownership. Table 2 shows results. Models 1 and 4 include only our variable of interest and fixed effects; Models 2 and 5 add industry-level covariates; and Models 3 and 6 add country-level covariates. In all models, the sign on EFFECTIVE CASH TAX RATE (FOREIGN) is as predicted: it is positive for foreign firms (Models 1-3) and negative for domestic firms (Models 4-6). The coefficient on EFFECTIVE CASH TAX RATE (FOREIGN) achieves significance at conventional levels in the fully specified foreign model (Model 3) and in the domestic model with industry-level controls (Model 5). Thus, results are consistent with the theoretical model, which provides us confidence because, as discussed, taxes are an imperfect proxy for government treatment. Additionally, recall that our sample of domestic firms is biased toward more-productive firms, as each domestic parent company in the sample must be listed and have a subsidiary in the home country, in addition to the parent company's official headquarters. We find the consistent negative signs and at or near significance in Models 4-6 particularly compelling given this skewed sample. Regarding control variables, STARTUP COSTS (FOREIGN) are associated with lower productivity and STARTUP COSTS (DOMESTIC) are associated with higher productivity, whereas the relationships for MOBILE are flipped. While our theoretical models does not generate clear predictions for these variables in this context, we note that the flipped signs reinforce that these variables are not measuring the same underlying concept.

[Table 2 goes here.]

⁴⁶In general, outcomes of interest are robust to using ordinary least squares, although significance varies. See replication files.

In our tests of Hypothesis 2, government behavior is now the outcome to be explained. Note that in Table 3 we have split the ratio that measures the government takings rate, using FOREIGN CASH TAX EXPENSE on the left-hand side and PRETAX INCOME on the right-hand side. Why? In Table 2, we tested the effect of tax expenses per income on outputs per inputs. In that case, per our theory, a rate (of takings) determines a rate (of return). In contrast, per Hypothesis 2, the outcome of interest is government behavior. As emphasized above, it is key to our theory that we find a political effect of startup costs that does not operate through firm size. It should not be that firms in industries with high startup costs are simply bigger. Thus, if we use the takings rate as the dependent variable, our concern is that startup costs could generate change in the ratio via changes in the denominator (income) rather than the numerator (the amount the government takes). To accurately test our theory, we must uncover a political effect of startup costs when holding income in a country-industry-year steady. This requires us to control for size rather than scale the dependent variable by size.⁴⁷

[Table 3 goes here.]

See Table 3 for results. As before, Model 1 is a stripped-down specification, Model 2 adds industry-level covariates, and Model 3 adds country-level covariates. In all models, we find the hypothesized negative association between STARTUP COSTS (FOREIGN) and FOREIGN CASH TAX EXPENSE at the industry level, with a high degree of confidence and a consistent coefficient size. The association holds even when controlling for PRETAX INCOME in Models 2 and 3.⁴⁸ These strong results provide support for what we see as the key political takeaway of our model that emphasizes the importance of entry. Table 3 also highlights our contribution as a complement to predictions about the effect of MOBILE. Both the literature and our model predict that the coefficient on MOBILE should be negative and significant. While true in Model 2, the sign flips in Model 3. Though we emphasize again how rough our mobility measure is, these results suggest that obsolescing bargain expectations are not fully robust in this setting. When included side-by-side with mobility, our theoretically novel (continuous, and precise) measure of startup costs offers improved explanatory power.

⁴⁷Signs are as expected but significance is not robust if we mis-specify the model and use the ratio as the dependent variable.

⁴⁸The signs on PRETAX INCOME are insignificant but nonetheless negative, suggesting that higher average pretax income for a foreign firm in a given industry might be associated with lower average actual tax outlays. These results reinforce that the relationship between multinational corporations' actual tax expense and the tax burden implied by firm income is not straightforward. For example, bigger firms may be able to adjust actual tax payments over time through creative, resource-intensive accounting efforts in ways that smaller firms cannot.

To reinforce our political results, we explore the implications of our model for economic relationships between startup costs, productivity, and revenue. Again, these tests are particularly useful, because while they do not directly measure political relationships, support for Hypotheses 3 and 4 provides important corroboration for the political dynamics we predict per Hypotheses 1 and 2. First, Hypothesis 3 specifies the expected relationship between startup costs and productivity for mobile foreign firms. We find support in Table 4: within the overarching category of mobile industries, higher `STARTUP COSTS (FOREIGN)` are significantly associated with higher average industry-level `RETURN ON ASSETS`. Results in Table 4 are particularly important, because the underlying causal mechanism operates through the takings rate but does not require us to measure or control for the takings rate. Our theory establishes that startup costs have a direct economic effect by deterring entry by low-productivity foreign firms. At the same time, deterred entry reduces replaceability and thus leads the government to take less. But when firms are mobile, the government is already taking less because of the obsolescing bargain dynamic, such that any additional political effect of startup costs should be dominated by the economic effect. The positive coefficient on `STARTUP COSTS (FOREIGN)` is consistent with this reasoning. Moreover, this evidence in support of Hypothesis 3 further establishes that startup costs can explain variation of interest beyond mobility alone.

[Table 4 goes here.]

Finally, analyses reported in Table 5 test Hypothesis 4, the relationship between `STARTUP COSTS (FOREIGN)` and foreign firm `REVENUE`. Higher industry-level `STARTUP COSTS (FOREIGN)` are associated with significantly higher foreign firm-level `REVENUE` in Models 1-3. The coefficient is positive for foreign subsidiary-level revenue as well, although it misses significance. Again, this evidence supports a key implication of our theoretical model without requiring us to measure government takings. Because higher startup costs deter new foreign firm entry, they reduce competition, increase prices for consumers, and lead to higher revenues for those firms “in” the market. The government, too, is pressured to provide more favorable treatment to foreign firms given the fewer available replacements. Both mechanisms lead to higher revenues. Importantly, this expectation holds at the level of the firm, so we find support for the theory without needing to calculate industry-level averages for the dependent variable. Results on `MOBILE` are mixed, again reinforcing the importance of our theoretical expectations derived from theorizing endogenous entry.

[Table 5 goes here.]

Results of interest are robust to a number of different modeling choices, three of which are worth particular emphasis.⁴⁹ First, to alleviate the concern that government treatment varies systematically with corruption, results are robust to controlling for a continuous measure of corruption, or splitting the sample by high or low corruption (World Bank WDI). Second, as is standard, we assume in our formal model that consumers prefer variety, such that the elasticity of substitution across goods within an industry (σ) is greater than 1. For robustness, we include a measure of σ at the 4-digit NAICS level in all specifications, although this restricts the sample size (Broda and Weinstein, 2006; Kim and Zhu, 2016). The measure of σ itself does not reach significance and its sign is somewhat unstable, while results of interest are generally as expected. The exception is that results of interest in Table 4 do not replicate. Recall that this analysis selects on foreign firms that operate in mobile industries (per the dichotomous measure). When including σ , the average startup cost faced by a foreign firm in a given country-industry is no longer associated with a higher average return on assets in that country-industry. Our takeaway from this failed robustness test is to acknowledge the multi-layered selection issues at play in this particular permutation and to return to the weight of the evidence as established by a multitude of other tests.

Third, while we already account for firm size in our specifications, we endeavor to do more to control for firm-level characteristics. Our results are robust to including fixed effects for FIRM STATUS, placing each firm in one of five categories: active and listed; active but delisted; in insolvency proceedings; in bankruptcy; or in liquidation. This allows us to compare within groups of firms enjoying similar levels of success. However, recall that firms must be active and listed to be present in the sample; any other firm status occurs after the firm has incurred startup costs in the host country. If we think of startup costs as the “treatment” that shapes outcomes of interest, then any status other than active and listed is post-treatment. Thus, while we see FIRM STATUS as the least bad alternative with regard to post-treatment bias among other possible firm-level controls, we exclude it in our main results.⁵⁰

In sum, we are reassured by direct support for the political components of our theory, which are our focus. We find compelling evidence that higher foreign startup costs are associated with more favorable government treatment, and that the selection effects generated by higher foreign takings raise the average productivity of foreign firms in the market and lower the average

⁴⁹See replication files for results.

⁵⁰Because managerial decisions over hiring practices would be made in the context of known startup costs, firm-level employee-based measures would also be post-treatment.

productivity of domestic firms in the market. We do so by using a novel measure of government treatment—the industry-average tax burdens facing foreign firms in a given country-year. Our confidence in the theory is further strengthened, because we find strong support via indirect tests focused on economic implications of our political arguments. Finally, our theory explains variation in outcomes of interest beyond that possible with a sole focus on asset mobility. Endogenizing entry is thus not only theoretically but also empirically important.

5 Conclusion

Our main contribution in this paper is to draw out the political effects of startup costs on host governments' treatment of foreign firms. Our approach highlights that market entry conditions play a crucial role alongside asset mobility and market exit, which have been the focus of previous scholarship. When startup costs are high, host governments must take less lest they deter existing and potential foreign firms. Both direct and indirect empirical tests of our argument support our main conclusion: when it is more expensive to enter a market and start up new production, those foreign firms that are capable of doing so enjoy improved government treatment.

One implication of our theory pertains to technology. If different technologies advance at different rates, today's ranking of low and high startup costs will likely someday change. Our theory implies that the distribution of government treatment across industries would change as well. Consider the startup costs of small-scale, manual-labor-based farming in the past versus the large-scale, capital-intensive farming of the present. Our theory is consistent with both today's lower risk of agricultural land expropriation in the United States, as well as the fact that highly productive multinational corporations now dominate the agricultural industry. Our approach can thus provide insight into both variation in government treatment across countries and changing patterns of treatment over long time horizons.

Our theory also pushes a new research frontier that emphasizes government tradeoffs between promoting foreign versus domestic firms. This tradeoff is especially salient as domestic firms originating in developing countries become multinationals. Competition between foreign and domestic firms is also important given normative concerns about the impact of FDI and international investment law on the advancement of domestic entrepreneurship in developing countries.

In this article, we defend our measure of startup costs: it is simply far more expensive to build a new factory complex than it is to rent office space to start a software company. We aim to identify effects of exogenous industry-average variation in startup costs that outweigh endogenous

adjustments at the margin. Future research can build on our approach to examine the impact of host governments' efforts to endogenously manipulate startup costs at entry, for example, via investment incentives (Jensen and Malesky, 2018). Additionally, one could consider the differences in government treatment generated by variation in treatment at entry and variation generated over the long-run as bargains obsolesce. Our approach suggests that, so long as replaceability is high, adverse treatment expected in the long-run can in fact come quickly.

Finally, big, multinational corporations might protest our findings. These multinationals make headlines with outspoken complaints about the vicissitudes of government treatment in a globalized era.⁵¹ But the perception that big, productive multinationals face all or even most investor-state conflict is flawed. Their observable complaints are the result of deep and layered selection effects. We argue that these loud multinationals are exactly the productive firms in expensive industries that in fact enjoy better government treatment on average. In stark contrast, foreign firms that operate in industries with lower startup costs have lower revenues, are less productive, and face poorer average government treatment.

⁵¹For example, the biggest multinationals find the most success in international litigation against sovereign host states. Foreign investors with over US\$1 billion in annual revenues, and especially investors with over \$10 billion, win more compensation, more often than smaller firms when they sue host states over adverse treatment in Investor-State Dispute Settlement (ISDS) investment arbitration proceedings (Van Harten and Malysheuski, 2016).
